Iliotibial Band Syndrome: A Common Source of Knee Pain
RAZIB KHAUND, M.D., Brown University School of Medicine, Providence, Rhode Island
SHARON H. FLYNN, M.D., Oregon Medical Group/Hospital Service, Eugene, Oregon

Iliotibial band syndrome is a common knee injury. The most common symptom is lateral knee pain caused by inflammation of the distal portion of the iliotibial band. The iliotibial band is a thick band of fascia that crosses the hip joint and extends distally to insert on the patella, tibia, and biceps femoris tendon. In some athletes, repetitive flexion and extension of the knee causes the distal iliotibial band to become irritated and inflamed resulting in diffuse lateral knee pain. Iliotibial band syndrome can cause significant morbidity and lead to cessation of exercise. Although iliotibial band syndrome is easily diagnosed clinically, it can be extremely challenging to treat. Treatment requires active patient participation and compliance with activity modification.

Most patients respond to conservative treatment involving stretching of the iliotibial band, strengthening of the gluteus medius, and altering training regimens. Corticosteroid injections should be considered if visible swelling or pain with ambulation persists for more than three days after initiating treatment. A small percentage of patients are refractory to conservative treatment and may require surgical release of the iliotibial band.

Iliotibial band syndrome is a common knee injury that usually presents as lateral knee pain caused by inflammation of the distal portion of the iliotibial band; occasionally, however, the iliotibial band becomes inflamed at its proximal origin and causes referred hip pain. The iliotibial band is a thick band of fascia that is formed proximally by the confluence of fascia from hip flexors, extensors, and abductors. The band originates at the lateral iliac crest and extends distally to the patella, tibia, and biceps femoris tendon (Figure 1).

The iliotibial band is a thick band of fascia that extends along the lateral thigh from the iliac crest to the knee. Iliotibial band syndrome occurs frequently in runners or cyclists, and is caused by a combination of overuse and biomechanical factors. The syndrome can cause significant morbidity; however, most patients respond to a conservative treatment approach that involves stretching and altering training regimens.

**Etiology**

Iliotibial band syndrome is caused by excessive friction of the distal iliotibial band as it slides over the lateral femoral epicondyle during repetitive flexion and extension of the knee resulting in friction and potential irritation. In patients with iliotibial band syndrome, magnetic resonance imaging (MRI) studies have shown that the distal iliotibial band becomes thickened and that the potential space deep to the iliotibial band over the femoral epicondyle becomes inflamed and filled with fluid.² Despite a clear pathophysiology, it is unclear why this syndrome does not affect all athletes. Few studies³–⁷ have shown any direct relationship between biomechanical factors and the development of iliotibial band syndrome. Excessive pronation causing tibial internal rotation and increased stress in the iliotibial band was believed to be a factor in the development of iliotibial band syndrome; however, the literature does not support this theory. Some observational studies⁴,⁶ have identified potential risk factors for the development of iliotibial band syndrome, including the following: preexisting iliotibial band tightness; high weekly mileage; time spent walking or running on a track; interval training; and muscular weakness of knee extensors, knee flexors, and hip abductors. Hip abductor weakness seems to contribute to the development of iliotibial band syndrome. Strengthening of the hip abductors has led to symptom improvement.⁶

**Clinical Presentation**

The primary initial complaint in patients with iliotibial band syndrome is diffuse pain over the lateral aspect of the knee. These patients frequently are unable to indicate one specific area of tenderness, but tend to use the palm of the hand to indicate pain over the entire lateral aspect of the knee. With time and continued activity, the initial lateral achingness progresses into a more painful, sharp, and localized discomfort over the lateral femoral epicondyle and/or the lateral tibial tubercle. Typically, the pain begins after the completion of a run or several minutes into a run; however, as the iliotibial band becomes increasingly irritated, the symptoms typically begin earlier in an exercise session and can even occur when the person is at rest. Patients often note that the pain is aggravated while running down hills, lengthening their stride, or sitting for long periods of time with the knee in the flexed position.⁷

**Differential Diagnosis for Lateral Knee Pain**

Physical Examination

Patients with iliotibial band syndrome often demonstrate tenderness on palpation of the lateral knee approximately 2 cm above the joint line. Tenderness frequently is worse when the patient is in a standing position and the knee is flexed to 30 degrees. At this angle, the iliotibial band slides over the femoral condyle and is at maximal stress, thus reproducing the patient's symptoms.\textsuperscript{1,6} Swelling may be noted at the distal iliotibial band and thorough palpation of the affected limb may reveal multiple trigger points in the vastus lateralis, gluteus medius, and biceps femoris. Palpation of these trigger points may cause referred pain to the lateral aspect of the affected knee. Strength of the lower extremity should be assessed with particular emphasis on examining the knee extensors, knee flexors, and hip abductors. Weakness in these muscle groups has been associated with the development of iliotibial band syndrome.\textsuperscript{4,6,7}

The Ober's test can be used to assess tightness of the iliotibial band (Figure 2). With the patient lying on the side with the unaffected side down and the unaffected hip and knee at a 90-degree angle, the examiner stabilizes the pelvis, then abducts and extends the affected leg until it is aligned with the rest of the patient's body. The affected leg is lowered into adduction. If the iliotibial band is normal in length and unaffected, the leg will adduct and the patient will not experience pain. If the iliotibial band is tight, the leg will remain in the abducted position and the patient may have lateral knee pain.\textsuperscript{1,6,8} A tight iliotibial band contributes to the excess friction placed on the iliotibial band as it slides over the femoral condyle during flexion and extension of the knee.

![Fig. 2](image)

**Figure 2**

Ober's test. The patient lies down with the unaffected side down and the unaffected hip and knee at a 90-degree angle. If the iliotibial band is tight, the patient will have difficulty adducting the leg beyond the midline and may experience pain at the lateral knee (arrows).

A clinical diagnosis is based on the history and physical examination. If the diagnosis is in doubt or other joint pathology is suspected, MRI can aid in the diagnosis and provide additional information about patients considered for surgery. In patients with iliotibial band syndrome, MRI shows a thickened iliotibial band over the lateral femoral epicondyle and often detects a fluid collection deep to the iliotibial band in the same region.\textsuperscript{2}

Treatment

Treatment requires activity modification, massage, and stretching and strengthening of the affected limb. The goal is to minimize the friction of the iliotibial band as it slides over the femoral condyle. The patient may be referred to a physical therapist who is trained in treating iliotibial band syndrome. Most runners with low mileage respond to a regimen of anti-inflammatory medicines and stretching; however, competitive or high-mileage runners may need a more comprehensive treatment program.

The initial goal of treatment should be to alleviate inflammation by using ice and anti-inflammatory medications. Patient education and activity modification are crucial to successful treatment. Any activity that requires repeated knee flexion and extension is prohibited. During treatment, the patient may swim to maintain cardiovascular fitness. If visible swelling or pain with ambulation persists for more than three days after initiating treatment, a local corticosteroid injection should be considered.\textsuperscript{6} (Figure 3).
Corticosteroid injection for iliotibial band syndrome. Gerdy's tubercle and the femoral condyle are marked as landmarks. With the patient in a supine or side-lying position, the needle is inserted at the point of maximum tenderness over the femoral condyle.

As the acute inflammation diminishes, the patient should begin a stretching regimen that focuses on the iliotibial band as well as the hip flexors and plantar flexors. The common iliotibial band stretches (Figure 4) have been evaluated for their effectiveness in stretching the band. The stretch shown in Figure 4C was consistently the most effective in increasing the length of the iliotibial band in a study of elite distance runners. Although this study demonstrates the effectiveness of stretching the iliotibial band, participants in the study did not have iliotibial band syndrome and studies have not demonstrated that stretching hastens recovery from the syndrome.

Once the patient can perform stretching without pain, a strengthening program should be initiated. Strength training should be an integral part of any runner's regimen; however, for patients with iliotibial band syndrome particular emphasis needs to be placed on the gluteus medius muscle. A strengthening exercise geared toward the gluteus medius is shown in Figure 5.
Exercise for strengthening of the right gluteus medius muscle in a weight-bearing position. (A) The patient stands on a platform and lowers the left leg toward the ground slowly. (B) Through contraction of the right gluteus medius, the patient then elevates the leg, returning the pelvis to a level position.

Running should be resumed only after the patient is able to perform all of the strength exercises without pain. The return to running should be gradual, starting at an easy pace on a level surface. If the patient is able to tolerate this type of running without pain, mileage can be increased slowly. For the first week, patients should run only every other day, starting with easy sprints on a level surface. Most patients improve within three to six weeks if they are compliant with their stretching and activity limitations.

For patients who do not respond to conservative treatment, surgery should be considered. The most common approach is to release the posterior 2 cm of the iliotibial band where it passes over the lateral epicondyle of the femur. In a retrospective study of 45 patients who underwent surgical release of their iliotibial band, 84 percent of the patients reported that their surgery results were good to excellent.

The Authors

RAZIB KHAUND, M.D., is clinical assistant professor of medicine in the Department of Orthopedic and Internal Medicine at Brown University School of Medicine, Providence, R.I., a physician in internal medicine at the Hughston Clinic in Columbus, Georgia, and a sports medicine specialist at the New England Center for Athletes in Providence. Dr. Khaund received his medical degree from New Jersey Medical University, Newark. He completed a fellowship in sports medicine at the Hughston Clinic.

SHARON H. FLYNN, M.D., is a hospitalist at the Oregon Medical Group/Hospital Service, Eugene, Ore., and has a special interest in sports medicine. She received her medical degree from George Washington University Medical Center, Washington, D.C., and completed a residency in internal medicine at Rhode Island Hospital/Brown University School of Medicine.

REFERENCES

Iliotibial band syndrome. The IT band is a thick band of fascia that starts at the hips and runs the entire length of your leg, connecting to the outside part of the patella (knee cap), tibia, and lateral hamstrings (biceps femoris tendon). This pain usually presents on the lateral part of the knee and is caused by excessive compression of the band as it pushes into the fat pad that covers the prominent bony part of the femur (lateral epidondyle). Symptoms often grow over time and aren’t often linked to one specific incident or trauma (like getting hit on the side of the leg). Iliotibial band syndrome: a common source of knee pain.
